## COST/BENEFIT ANALYSIS OF THE HEAT RECOVERY INCINERATOR (HRI)

This report discusses the sensitivity of heat recovery incinerator (HRI) cost/benefits to various techno-economic parameters associated with the HRI computer model. These sensitivity data are presented in a form to aid in the conceptual design of the optimum HRI facility for a given Navy activity. The following techno-economic parameters are listed in order of their expected importance, considering both variance and sensitivity, to cost/benefit criteria of the HRI computer model: solid waste heating value, boiler thermal efficiency, energy inflation rate with respect to general inflation, cost of conventionally generated steam, solid waste disposal cost, differential landfill inflation of disposal cost, capital cost, and ratio of ash to waste input. Naval Facilities Engineering Command policy regarding HRI construction at Navy activities is to seek alternative waste management opportunities such as the use of nearby resource recovery facilities that have been financed and erected by private operators or civic entities.

#### INTRODUCTION

The Naval Facilities Engineering Command (NAVFAC) has tasked the Naval Civil Engineering Laboratory (NCEL) to evaluate the heat recovery incinerator (HRI) technology for application to Navy shore activities. NCEL has developed criteria to be used as guidance in determining whether a Navy activity can benefit economically from the use of an HRI in disposing of solid wastes. These decision criteria have been incorporated into a publication titled "Heat Recovery Incinerator (HRI) Application Guide" (Ref 1).

The HRI model was one of the tools developed by NCEL to facilitate the use of the HRI Application Guide. The model determines the economic liability or profitability of conceptual candidate HRI plant designs for a given Navy activity. The model also dimensions the influence of the various techno-economic factors on the cost/benefit results for the conceptual HRI facility when it is operational. This analysis will be used in the decision-to-construct process.

This report presents data on the correlations (and their sensitivities) that exist between the major design techno-economic parameters and a conceptual plant's economic viability. These data result from systematic exercising of the model. These sensitivity data are presented so that, in conceptually designing the optimum candidate HRI facility sought for a given Navy activity, the responsible design engineer will fully appreciate and take advantage of the way individual techno-economic factors impact the ultimate cost/benefit pay-offs. In this way, the ultimate decision to construct or abandon an HRI project will be made only after faulty system designs have been identified and corrected. Some Navy HRI projects have been approved and others rejected on the basis of questionable system designs. The study reported here provides a more logical and consistent approach.

#### **BACKGROUND**

The HRI Application Guide was specifically developed to provide a logical approach whether to install an HRI plant. The HRI Application Guide tells the user how to proceed systematically through a diagrammed decision matrix wherein data requirements that must be input for the decision process are developed at three progressively refined levels of iteration. In this data development and analysis process, the HRI Model is a tool that serves to determine as to whether a conceptual HRI candidate project would be cost beneficial relative to the processes already in place for waste disposal and steam generation.

Use of the HRI Model on a microcomputer is explained in the NCEL terminal-handbook, "User's Manual for the Heat Recovery Incinerator (HRI) Model" (Ref 2). The model assumes that solid waste is disposed of in a

landfill and that some kind of fossil fuel is being burned to generate steam for use at the Navy activity; either of these processes may be internal or contracted services. The model does not consider the HRI as being coupled to a turboelectric generator since, in order to be cost effective, the solid waste throughput would have to be considerably more than the typical large Navy activity generates. The model also assumes that the HRI has been selected for the primary function of disposing of sorted (possibly) but otherwise unprocessed solid waste (although cofiring of other waste and conventional fuels is permitted) and not as a system that has been designed primarily for fossil fuel firing with a secondary capability of firing specially prepared refuse derived fuels (RDF). Although not considered here, the latter scenario is now being studied at NCEL and should later lead to documentationt to: (1) identify any Navy-qualifiable RDF materials that are found to be reasonably marketable, and (2) define optimum usage of such materials in existing Navy boilers or in multiple-fuel-capable boiler designs now being considered by the Navy for future construction.

The various terms used in this report are defined in Appendix A. The techno-economic inputs called by the model will be discussed in some detail later but for immediate reference purposes are shown in Appendix B. The information format used in Appendix B actually comprises the input data screens presented to the user by the program. It can be seen in Appendix B that consideration is given to every aspect of facility design, construction, operation, reliability/availability/maintenance (RAM), and financing. As pointed out later, the values appearing on the screens are considered to be about what are average for an HRI plant installed at an average sized, typical Navy activity.

The outputs of the model are all tabulated on a single sheet, titled "The HRI Cost and Performance Report." This is presented as the last page of Appendix B. The program generates six categories of information, all of which are important to consider in deciding whether to install an HRI or to stay with the status quo. In the first category, the life cycle cost of the proposed system is computed by combining user inputs for the cost of capital, operation and maintenance, and system downtime due to failures. This cost is then compared to the sum of the costs of (1) using a conventional fossil fuel fired steam generator to produce the equivalent steam energy output for the HRI life cycle, and (2) disposal at a landfill of the solid waste that would be eliminated by operating the HRI.

The second category of model output information is the amount of limited-resource, prime (not reclaimed) fuel, such as petroleum fuels and natural gas, that is saved annually, as barrels of oil equivalent (BOE), by firing solid and possibly other wastes.

A third output category addressed by the model is the landfill capacity that is annually conserved by using the HRI. Because no practical disposal technique can completely eliminate the need for some landfill availability, conservation of landfills through maximum reduction of the waste volume is often economically important in the long term. However, if there are ample nearby landfill sites, an HRI project probably cannot be justified from the start.

This report also includes as a fourth category of information-output: the discounted life cycle costs and savings provided by the modelled HRI per ton of solid waste fired and per million Btus of steam generated. These data are very useful in making comparisons with other systems whether their function is basically one of waste disposal or of energy generation or both.

The two final output categories of the model are by far the most important. These are: Savings-to-Investment Ratio (SIR) and the HRI total payback period (including project lead-time). These, of course, are ultimate considerations in driving the decision process to the proper conclusion. Additionally, 13 other figures of merit are generated as outputs by the model that can be categorized together with one or the other of these two key parameters.

In the section following, the software of the HRI model is briefly described and introduced for optional study as an appendix. In the subsequent section of this report, the results of the sensitivity analyses performed are presented. The empirical functions describing the relationships of the techno-economic input variables with respect to selected parameters from each of the six output categories just discussed are tabulated and graphically presented. Comments on the significance of these operators in considering preliminary plant designs, operating cycles, and future changes in disposal practices are included in the discussion.

#### THE HRI MODEL SOFTWARE

The computer program of the HRI model is listed in Appendix C. The language is BASIC and is assembled for use in CP/M mode on a floppy disk microcomputer equipped with two disk drives. The software was developed on an Apple II computer and has been debugged and extensively exercised on the same type microcomputer.

The costing practices observed in the development of the HRI Model software are in conformity with NAVFAC P-442 (Ref 3). A possible exception is the specification of a 15-year life expectancy for the HRI plant, but this is only provided as a default value. The user is free to input any project lifespan he wishes, including the 25-year facility life specified in P-442 for conventionally fueled steam generators.

The mathematical subroutines effected by the HRI Model in achieving output results are explained in Reference 2. Appendix C may be consulted if a more detailed study of the techno-economic functions is desired.

#### THE HRI BASE CASE EXERCISED IN THE ANALYSIS

In order to evaluate the interrelationships of the input/output (I/O) model parameters, it was necessary to select some base case to represent the typical HRI plant that would fit the requirements of the average Navy activity. The accuracy of the definition of this base case is actually not critically important since small deviations from true average values do not significantly affect the comparative relationships (functions) of the I/O parameters with respect to each other but only

offset to some varying degree the relative scaling of each. If these deviations from true averages assume larger proportions, then the parametric relationship can be affected, but only if the functions are nonlinear.

The values assigned for the model case are shown on the HRI Model input screens which, as mentioned earlier, are tabulated herein as Appendix B. A brief explanation of the use of the input data follows.

Screen 1--The inputs for current month and year represent the actual time the analysis is performed. Inflation rates are specified and reflect any differential rates that may operate between the factors considered in the analysis. Inflation rates are applied to the variously dated input costs until initial funding occurs when standard NAVFAC P-442 discounting is observed. Project lead time allows for distribution and discounting of the involved costs over the project lead time period. The economic life of the HRI is its expected term of beneficial occupancy. As noted earlier, this has been set at 15 years rather than the 25-year period specified for steam generators in NAVFAC P-442 because of the more deleterious stoking/combustion conditions that HRIs experience in comparison to fossil fuel fired boilers.

Screen 2--Capital costs shown on this screen are dated and broken down into discrete categories. This is an optional journal procedure since line item entrees are ignored by the model in favor of subtotals. Similarly, subtotals are ignored if an entry for Total Capital Costs is made at the top of Screen 3. Thus, in Appendix B the subtotals are entered while the line items are not journalized.

Screen 3--In addition to total capital costs, allowances are made for expected major modifications of the plant. These can be dated up through the entire economic life of the plant and will be accordingly discounted. The type of modifications can include both augmentative and restorative operations, for example, plant expansion through the addition of a new boiler or installation of new refractory in the HRIs, respectively.

Screen 4--Manpower requirements are broken down into operation and preventive/corrective maintenance. Wage rates are burdened to allow for fringe benefits and acceleration, which amounts to about 40% incrementation of pay scale. Full burdening as done at NIFI activities is not considered applicable since the inputs to the model itself consider the overhead charges normally going onto NIFI burdens. Assignment of operational personnel to maintenance procedures during outages is taken into account. The assumption is that the balance, if any, of their time will be reassigned to other duties and will not be assessed against HRI O&M.

Screen 5--Cost of consumables includes all requirements for the plant. Power consumption takes into account the plant mode of operation. Fuel usage, for auxiliary firing and operation of ancillary equipment such as front-end loaders, is broken down into "virgin" and other fuels. The former type fuels are those that the Navy seeks reduced usage of (fuel oils and natural gas), while the "other" category includes fuels that offset the virgin fuels and can include waste fuels (e.g., JP fuels rejected as being out of specification), other solid waste fuels (bagasse, wood chips, etc.) and fossil fuels that are domestically in potential long supply, such as coal, peat, shale oil, and the various coal derived fuels.

Screen 6--In addition to several more maintenance cost factors, costs are given for solid waste disposal. These costs are broken down into the three categories of waste that the HRI is involved with, which include nonburnable waste, ash, and as-received material. Disposal costs for the latter represent a saving when the HRI is operating but become a debit if the HRI is down and must divert waste.

Screen 7--Other costs are special entries that can include capital (C), energy (E), landfill (L), or other (O) costs. These may be input as fixed or conditional modifications after a model case has been developed. For the present exercise, Screen 7 was not used.

Screen 8--Many of the key design and operational factors are input to this screen and are largely self-explanatory. A possible exception is the specification of furnace type (refractory or water walled). This input implements a procedure for correcting for the differences in wall heat losses of the two furnace types when shut down during scheduled or unanticipated outages. Also the mathematical application of estimated maximum HRI downtime may not be obvious. The distribution of HRI downtimes is assumed to be log-normal and the user's estimate of the maximum duration of downtime is required to scale that function.

#### THE ANALYTICAL APPROACH

This section describes the approach used to determine how the various operating and cost factors (input parameters to the HRI model) affect the cost benefits of an HRI plant. The HRI cost benefit analysis program described above is essentially intended for the analysis of a specific HRI installation, which some user or user's consultant has developed as being appropriate to his particular activity. On the present undertaking, the specific conceptual HRI plant usually input to the model was replaced with the base case HRI. The program was then repetitively run with the selected parameters being varied over predetermined ranges at arbitrarily fixed intervals.

The summary report sheets obtained from these exercises were then plotted using the Tektronix 4052 ADP plotting system. Empirical equations were generated by polynomial regression by the same computer/plotter for each of the curves generated. These expressions were abbreviated to eliminate inconsequential terms and are tabulated here as Appendix D. These equations may be used to predict the behavior of the particular variable beyond the range examined in this study. The user should, however, be aware of the possibility of incurring significant error when empirical equations are exercised outside of the range in which they were developed.

The input data for the base HRI case were derived from existing HRI facilities costs and construction and operating conditions (e.g., Ref 4) and provide a reasonable reference point from which to execute variations in the input parameters. The independent variables were usually operated over rather broad ranges, ones that would not likely be exceeded in actual engineering practice. In most cases, the range of variation has been arbitrarily assigned and generally is not more then 50% above or below the base case value.

The independent variables that are discussed in this section have been divided into the following four groups: (1) costs, (2) inflation rates, (3) plant performance, and (4) other design criteria. Each group is individually discussed, with particular emphasis being given the comparative impact on cost benefits each of the group members was found to exhibit.

#### HRI COSTS

The first group of independent variables comprises cost parameters which include: capital costs, disposal costs, and cost of producing steam from an existing fossil fuel boiler.

#### HRI Capital Costs

Heat recovery incinerator capital costs refer to the total equipment and construction expenses for erecting an HRI plant. In addition to entering the capital cost figures, the year in which the money is anticipated to be spent must also be entered into the computer model, since inflation factors need to be applied to such costs.

Capital costs are a major fraction of the total investment cost of an HRI facility. As shown in Figures 1 and 2, the discounted life cycle cost (LCC), discounted life cycle savings (LCS), and payback period (the number of years required for the savings to equal the costs) all vary linearly with varying capital costs. The savings-to-investment ratio (SIR) decreases exponentially with increasing capital cost, approximated by a second order function. Because the rate of change for a second order curve is dependent on the specific location of the point on the plot, the accuracy of the capital cost value used is important in estimating its effect on SIR (unlike LCC, LCS, or payback period). While the data used are indeed of reasonable accuracy, the variations are essentially manipulations that would not likely occur within a population of properly designed HRI plants. The competitive bidding process would likely ensure that the average (stabilized) dollar cost for a given HRI purchase specification package would not vary greatly from one CONUS activity to another. The key lesson that is to be learned from Figures 1 and 2 is that designers should avoid frills, excessive redundancy, overdesigned components, and other liberalities that can drive capital costs up and render the resultant facility cost-ineffective.

#### Solid Waste Disposal Costs

In contrast to the somewhat artificial variation in capital costs practiced above, a variation in disposal costs is a very real and expectable thing. The scale range used (\$0-50) is not heavily exaggerated, since costs of landfill disposal may soon approach the \$50/ton level in certain parts of the country. Landfill disposal costs are, in fact, one of the principal factors incentivizing solid waste managers towards the construction of waste-to-energy plants.

Fortunately, however, the sensitivity of payback and SIR to variations in disposal costs is not as acute as it is to capital costs. This is apparent from Figures I and 2. This is, of course, due to the predominant role capital costs play in the initial (lead time) investment term, which is the denominator in both of the above expressions. In contrast, LCC and LCS are more profoundly influenced by disposal costs (see Figure 2), since these cost benefit terms deal only with the discounted costs and savings which are accrued over the entire economic life of the plant.

The fact that the difference between LCS and LCC does not appear to change over the range of disposal costs observed merely results from the fact that disposal costs for ash, oversized, and noncombustibles are also increasing, assumedly at the same rate as the regular disposal costs. Since the solid wastes emanating from the HRI are a fixed fraction of what is received, the slopes of the LCS and LCC curves should thus be the same, if all other factors remain the same. It will be noted that the difference in LCC and LCS is less than the capital cost of the base case; this does not mean, however, that the plant will be unprofitable. The capital cost is not a discounted value and cannot therefore be directly compared. The magnitude of the difference does, however, point up the justification for recovering energy in the process of reducing disposal volume.

#### Cost of Producing Steam From an Existing Fossil Fuel Boiler

Another cost that is an input parameter to the HRI model is that for operating a pre-existing fossil fuel boiler to provide the same amount of steam energy that would result from the operation (zero downtime) of the HRI design selected for input to the model. The input includes the cost of steam produced by the fossil fuel boiler in units of dollars per million British thermal units (MBtu), and the year for which this cost was derived. This implies that the user knows what he is paying for steam, a cost easily determined only if the steam is bought from the outside. If it is produced by the PWD utility division, the cost will not be so easily fixed, since typically only fuel costs, unburdened operating labor costs, and repair bills are recorded. Some activities do maintain comprehensive steam cost data that include life cycle costs of plant, maintenance labor, labor burden, and many other cost items. Based on such data, the standard case value entered in the model was \$9/MBtu and was varied ±33% in the HRI study.

Given a competitively acquired and efficiently run fossil-fuel boiler plant that exhibits a RAM reasonably near the median, the principal operator that will impact steam cost is the cost of fuel. This, of course, is volatile enough that one could expect a range of variation in steam costs of the magnitude employed here. Thus, as one examines the strong reactions of the dependent cost/benefit parameters to fossil-fuel-based steam costs, one can essentially predict how the attractiveness of an HRI steam plant will be enhanced as fuel costs rise.

The behavior of the four dependent cost variables to fossil-fuel-based steam is shown in Figures 3 and 4. As could be expected, the HRI LC Savings (Figure 3) are dramatically influenced by changes in costs of conventionally generated steam. This is because HRI LC Savings are

derived from energy, waste disposal, and other savings. The energy term, which contains the cost of steam conventionally generated and HRI total energy costs, is a dominant factor. Thus, the attractiveness of the HRI investment will hinge critically on what an activity is already paying to generate steam. A well-managed, coal-fired plant will likely prove hard competition, thus making the other HRI LC Savings factors (e.g., high solid waste disposal costs) prime movers in the decision-to-construct process.

Discounted Life Cycle Cost of the HRI proves much less sensitive (Figure 3) to cost of conventionally generated steam. This is because the steam term only enters the comprehensive cost-of-doing-business expression in the downtime cost. Thus, a 33% increase in cost of conventionally generated steam increases the HRI LC Cost by less than 7%. A similar situation is obtained when looking at SIR (Figure 4). the HRI LC savings are essentially compared to inflation-normalized capital and engineering costs. Because the former term is dominated by the cost of conventionally generated steam and the HRI, in a right fit situation, is apparently an attractive investment otherwise, the SIR shows a strong response to steam cost variation. A 33% increase in the cost of generating steam from fossil fuel at a Navy activity will result in a 30% increase in the SIR for the modeled HRI plant displacing some of that production. The payback period is arithmetically more complicated than SIR even though the same economic expressions are involved. discounting process exponentiates the function, giving the result shown in Figure 4. Here a 33% increase in conventional steam cost will decrease payback period by only about 10%, while a like steam cost decrease results in a 23% increase in payback time. Because of this peculiar sensitivity and the earlier mentioned dominance of fuel cost on the cost of generating steam with fossil fuels, investment in an HRI must involve a hard look at probable future trends in fuel costs.

#### COST OF MONEY

In the foregoing discussion, the sensitivity of HRI costs normalized for inflation was discussed. In this subsection, the influence of inflation rates themselves is considered. Because the impact of inflation on capital and engineering costs is well known, project lead times are typically held to a minimum. What is often not considered is the effect on costs that differences in inflation rates between commodities have. Such differences are particularly noteworthy in the case of fossil fuel and solid waste disposal costs and can influence the cost/benefits of a project over its entire economic life.

In the present model, inflation rates allow for both a differential energy inflation rate and differential landfill inflation rate. These differential inflation rates allow the user to inflate energy or landfill costs at a higher rate than general inflation that is applied to the balance of the HRI cost components. Based on trends that operated at the time (but which today may well no longer apply), the two differential inflation rates were set at twice that of the general rate of inflation, which was taken to be 5%. These energy and disposal cost inflation rates, each thus set at 10%, were actually considerably less than what prevailed a few years ago.

#### Energy Cost Inflation

The differential energy inflation rate affects both the cost of operating the fossil-fuel fired steam generator with which the HRI is compared and the various quantities (sometimes none) of auxiliary fuel burned during start-up and, perhaps, routine operation of the HRI. For the present analysis, variation of energy inflation rate about the default value of 10% was not attempted because a stabilization of fuel costs had occurred after the default value was set. The variation applied, therefore, was to start the range at the general inflation rate of 5% and then increase it 10 percentage points above that to 15%. Thus, the inflation rate of 10% for energy and landfill disposal costs used in the standard case locates midpoint in the differential range. The results are shown in Figures 5 and 6.

It can be seen that the HRI Life Cycle Savings (LCS) increase dramatically with energy inflation rate while the increases in HRI Life Cycle Cost (LCC), while much less, are nonetheless at about the same rate as the energy inflation rate. The results are entirely analogous with those obtained when steam costs are varied. HRI LCS derive from conventional energy, landfill disposal, and "other" costs savings. Energy dominates in this relationship and the cost of fuel dominates energy costs such that inflation of energy costs (through fuel price increases) results in a skyrocketing appeal developing for the waste-to-energy concept.

#### Landfill Disposal Cost Inflation

The economic impact of the landfill disposal cost inflation rate is similar in principal with that of energy costs but not as potent. For example, as energy cost inflation increases above general inflation from 0 to 10 percentage points, HRI LCS increases 197% while the same parameter is increased by "only" 30% when solid waste disposal costs are increased by the same amount. This is consistent with the analysis discussed earlier concerning Figures 1 and 2 where it was found that the relative (no inflation) cost of solid waste disposal did have a modest impact on cost/benefit parameters.

#### PLANT PERFORMANCE

Plant performance, which is the third group of independent variables to which cost/benefit parameters are sensitive, includes the following factors: (1) thermal efficiency, (2) ratio of wet ash to solid waste input, and (3) operating scenario.

#### Thermal Efficiency

As used in the model, thermal efficiency is simply expressed as the ratio of the design rates of steam energy output to thermal energy available from the combustion of the solid waste and any auxiliary fuel. The HRI thermal efficiency proved to be one of the more potent input parameters, with only capital cost and conventional steam costs exhibiting a greater influence on cost/benefit parameters. The potency of this

parameter results from the direct relationship of efficiency to the savings of producing steam conventionally. Discounted LCC, LCS, payback period, and SIR are plotted against thermal efficiency (Figures 7 and 8) as it is varied from 40 to 70%. This range is somewhat improbable on the low end, in a Navy context at least, but achievable at the high end. Refractory furnace HRI's equipped with waste heat boilers typically furnish efficiencies between 55 and 65%. Water wall units, which are intrinsically less susceptible to wall heat losses, provide efficiencies in the range of 60 to 70%.

Because of the direct relationship with offset conventional steam production, the LCS for response to efficiency improvement is impressive. The LCS increases 65% as the efficiency is increased 30% relative from the selected minimum of 40%. Definite benefits, although not as arithmetically prominent, are also seen in the LCC, SIR, and payback period. The obvious lesson presented by these data is that boiler efficiency should not be merely regarded as a casual system characteristic, that a premium should be placed on high, sustainable boiler efficiency, and that guarantees for boiler efficiency must be secured.

#### Ash Outhaul/Disposal Rate

Another factor that is a measure of plant performance is the tons of wet ash produced per ton of solid waste input. This output-to-input ratio provides the basis for quantifying the amount of ash that must be "landfilled" - hauled to a landfill. Typical output-to-input ratios resulting from the reduction of waste weight range from 0.2 to 0.6, depending on the degree of fuel burnout and the moisture content of the ash, which is wetted by an appropriate means. Either end of this range is attainable by the various ash handling processes that are available. Because of the relationship of ash disposal to solid waste disposal, which has been shown earlier to have only a modest effect on the cost/benefit parameters, variation of the ratio also has minor impact, assuming that the cost of disposal for ash is the same as that for solid waste.

Figures 7 and 8 illustrate the performance of LCC, LCS, payback period, and SIR versus the ratio of wet ash output to solid waste input. These data were generated, however, with the assumption that ash can be landfilled at the same cost as ordinary refuse. Present environmental law on this is not clear and local regulations may differ considerably. If ash is not permitted to be disposed of in a Class 2 landfill and a hazardous dump must be used, the unit disposal cost could be two to five times higher, depending on location. The data shown, therefore, are for a best case situation. In this case, the data would suggest to the potential HRI plant operator that ash disposal costs are not important factors in the choice between wet or dry ash handling systems. This conclusion should be avoided until after specific ash disposal requirements have been established. The model, incidentally, segregates costs of disposing of oversized reject, ash, and unprocessed refuse so that the model user can study the economic impact of having to haul these various forms of waste to different types of dumps.

#### Operating Scenario

This phrase refers to the number of hours per day and days per week the HRI facility is scheduled to operate. The HRI model provides the user with five operating scenarios with which the user may match his own planned operating schedule. The purpose of inputting this information is to calculate the boiler reheat losses associated with scheduled downtime under the different shift arrangements. It is assumed that when the capital costs for the plant were arrived at, the sizing of the plant was already based on the operating scenario selected. Thus, the model cannot be used to determine the comparative attributes (other than heat loss) of the various scenarios.

In the standard case (Option 2 in the HRI model), the operation was based on working three 8-hour shifts a day (24 hours), 5 days per week. The other four options include burning two shifts, 5 or 7 days per week or three shifts, 7 or 4 days per week (following receipt of 1 day's refuse collection). Other operating scenarios are employed in the trade but are rather uncommon.

While the model cannot determine the comparative attributes of the various operating scenarios given a fixed set of operational requirements, it can be used to consider the cost benefits available if it is decided to expand the throughput of an existing HRI. If an operator is somehow confronted with an increased load of solid waste to dispose of and the activity can utilize the additional steam generated, the operator may opt to change the operating scenario rather than seek funding for the erection of new facilities. The model can then demonstrate the benefits available from these scenario changes. This can be done for any incremental increase in refuse input. In the present study, however, the standard case only was exercised, thus fixing the firing rate. That is, the standard case requires a refuse input rate of 250 tons/wk; therefore, a shift to 7-day continuous firing would require inputting 350 tons/wk.

Given the operating assumptions just stated, the SIR and payback period behave in relation to the five operating scenarios as seen in Figures 9 and 10. As expected, the results indicate that the total duty time is almost directly proportional to the cost benefits realized.

#### OTHER ECONOMIC FACTORS

The fourth and final group of economic factors includes: (1) solid waste heating value, (2) plant economic life, and (3) discount rate.

#### Solid Waste Heating Value

The calorific value of the fuel is expressed as the higher heating value (HHV) and will vary considerably depending on the composition of the solid waste. A probable HHV range for randomly sampled, unprocessed Navy solid waste would be between 3,500 and 6,500 Btu/lb. Besides geographic peculiarities, considerable fluctuation in the composition and, thus, the HHV of Navy activity solid waste can be expected from seasonal and even diurnal factors, as well as from the exercise of the activity's

mission (e.g., variation in ship berthings). Nonetheless, the annual average HHV for a given Navy activity, if determined in accordance with Reference 1, should prove fairly reliable for HRI design purposes. What this value turns out to be, however, can be significantly influenced by the resource recovery policies in practice at the given activity. Source separation of refuse components, such as boxboard, aluminum cans, bottles, garbage, etc., can have a significant effect on heating value.

Changes in solid waste management practices or any other factors that affect the annual average HHV of solid waste will have a pronounced effect on the economics of an HRI facility. This sensitivity results simply from the HHV's direct relationship to the quantity of steam generated from a given amount of solid waste. Shown on Figures 11 and 12 are the LCC, LCS, payback period, and SIR versus Btu per pound of solid waste input. The HHV range plotted has been limited to between 4,000 and 6,000 Btu/lb, since the annual average range will be much narrower than the range for randomly sampled values mentioned above.

It can be seen that the LCS and SIR increase at almost the same rate as HHV. LCC is much less influenced since HHV enters the HRI cost base only when downtime costs are computed. The richer the waste fuel, the more energy that must be generated by a standby fossil-fuel-fired boiler per unit of downtime. The lesson available from these data is that some caution should be exercised in resource recovery if an HRI is to be operated. Source removal of valuable inerts (aluminum and glass containers, nonferrous junk, etc.) beneficiates the fuel and is certainly commendable if the separation process otherwise pays for itself. Removal of combustible fractions, such as IBM cards, boxboard, newspapers, etc., is another matter and should be given some thought. Boxboard now sells for about \$80/ton if you can find a nearby salvor. For steam production, however, it will produce about \$65/ton, assuming an HHV of 6000 Btu/lb, 60% boiler efficiency, and a steam value of \$9/MBtu. Can you separate the boxboard and deliver it to the salvor for less than the differential of \$15/ton? Also, you know that the value of steam will doubtless continue to increase, but what about the price of reclaimed boxboard, which has always been very volatile?

#### Economic Life of the HRI Plant

Useful economic life of the HRI plant was specified as 15 years for the standard case HRI model that was exercised on this study. This differs from the 25-year lifespan specified in P-442 for steam generators in fossil fuel fired systems, which inherently offer better longevity. The HRI life period was selected based on the experience operators have had in the field with a variety of HRI configurations. Some have been surveyed in a few years (e.g., Naval Air Station, Jacksonville) while others have been steaming well in excess of 15 years.

Because the HRI Application Guide (Ref 1) sets out design guidelines for an optimally configured HRI, it can be assumed that considerably extended plant life expectancies will result for those in the Navy availing themselves of this technology. For that reason it was felt justifiable to exercise the standard case assuming an economic life of 25 years. The results are shown in Figures 11 and 12. As expected, extending the economic life had essentially no effect on payback period but almost commensurately increased the SIR and the (SIR-related) LCS by the same fractional amount of the life extension. The effect on LCC was considerably lower (about half) because, while O&M costs were extended another 10 years, capital costs did not change.

#### Discount Rate

The discount rate is the minimum attractive rate of return that the Government expects on their money spent on a project. Per P-442, 10% has been used for several years, but recent trends are towards the use of 7%. In view of this possible change, the HRI model was executed at both 7 and 10% discount rates. The sensitivity of the discount rate was found to be rather small in the case of payback period but increased SIR by 24% when the lower discount rate was applied. These data are shown in Figure 13.

#### FINDINGS AND CONCLUSIONS

#### General Findings

The 11 parameters selected to determine their degree of influence on the cost/benefits of an HRI plant are presented in Table 1. The expectable range of variation these parameters may operate over (corrected for general inflation) is shown together with the degree of sensitivity SIR will experience when these variations occur.

#### Key Parameters

The three parameters expected to vary and thereby affect the economic characteristics of an HRI plant the most are: (1) heating value, (2) boiler thermal efficiency available from design, and (3) differential of energy inflation rate with respect to general inflation. These parameters can be expected to have both a moderate to high degree of variation and a high impact on SIR. Although other parameters may exhibit greater influence on SIR per unit of change, the overall effect of these parameters on the cost/benefits of the HRI plant is greater.

#### Capital Costs

Capital costs and the cost of conventionally generated steam both have the potential for significantly altering the cost/benefits of an HRI plant. Any trends that may result in the technological lowering of the former (corrected for inflation) or inflating the latter will markedly enhance the economic attractiveness of the HRI.

#### Disposal Costs

Both the cost of solid waste disposal and the differential inflation rate of that service with respect to general inflation proved to be less influential in the HRI cost/benefit picture than was expected.

Similarly, SIR exhibited relatively low sensitivity to HRI ash outhaul cost variations, but this is based on treating the ash as a nonhazardous material, a categorization that may prove faulty.

#### Uncertainties

Assignment of appropriate values for the money discount rate and the facility economic life was an uncertain process. Both can have very strong effects on the economic attractiveness of an HRI plant and should be better defined.

#### RECOMMENDATIONS

#### Capital Costs

Because of the powerful effect capital costs have on the economic viability of an HRI plant, they should not be allowed to vary upward through the inclusion of unnecessary features, redundancy, control sophistication, structural overdesign, etc. Protect your investment through the inclusion of component performance guarantees so that fix-money need not be applied. Be sure your bidders represent the competitive field of good technology purveyors and that your purchase specification package faithfully follows the guidelines in Reference 1.

#### Disposal Costs

There is no magic breakpoint in the costs for solid waste out-haul/disposal at which one should turn to the HRI Model Users' Manual. Rates can be expected to increase as they follow general inflation and rise sharply when new landfills come on line. Anticipate these relocations, preferably by several years, by running the HRI Model based on expected disposal costs.

#### Cost of Conventionally Generated Steam

This will go up as fossil fuel costs increase or if new plant (replacement or add-on) capacity is in MCON planning. If the latter is the case, determine if an HRI would satisfy the service required and, if so, at what comparative cost. Fossil fuel other than coal will certainly increase in cost enough to warrant the annual exercise of the HRI Model.

#### HRI Thermal Efficiency

Because of lack of development in small waterwall HRI's, the HRI Application Guide necessarily recommends a specific configuration of the refractory-furnace HRI, a device considerably lower in thermal efficiency than the waterwall system. With this design penalty considered, it becomes very important to specify a system that is very well insulated and that furnishes average residual carbon values not exceeding 3 wt-%. A minimum thermal efficiency of 60% must be guaranteed for a suitable operating term (at least 1 year) based on testing procedures that conform to ASTM Committee E38.10 standards.

#### Ash Production

Given efficient HRI combustion (low residual carbon), the quantity of ash output by an HRI will largely be determined by the composition of the fuel and the degree of wetting the ash experiences. The HRI Application Guide does not recommend the use of a dry ash handling system but instead promotes the use of quench tanks for handling bottom residues. Wet ash handling results in the leaching of metals from the ash and this can be a significant economic factor when considering landfill costs. Disposal of bottom/fly ash is variously regulated and, in some states, the material is treated as hazardous waste (high cost disposal) unless the leachable heavy metals are below certain limits. It will therefore be important to learn local disposal requirements and expected future requirements. If ash leaching becomes important, the ash handling system design should promote it.

#### Heating Value of the Fuel

Because the HRI Application Guide recommends mass firing of the received solid waste, beneficiation of the fuel should be done by source separation and a minimum amount of hand culling at the HRI plant. Source separation specifications should encourage removal of valuable inerts but leave combustibles that demonstrably will provide a better financial return when fired than when recycled. Upgrading the calorific value of the fuel will develop the economic viability of the HRI system significantly.

#### Operating Scenario

The HRI Application Guide recommends designing an HRI that will be operated continuously over a 5-day work week.

### Appendix A

### DEFINITIONS FOR HRI COST AND PERFORMANCE REPORT

The cost and performance report presented by the HRI computer model prints out 22 parameters which may be useful in the design or economic evaluation of a Heat Recovery Incinerator. This appendix presents a discussion of how each output parameter is calculated and, where deemed necessary, what the output parameters represent as economic functions. The definitions are listed in the same order as they appear in the HRI Cost and Performance Report, which is shown at the end of Appendix B.

- 1. INFLATED PER TON COST OF DISPOSING WASTE OF THE TYPE GENERATED AT THE SITE TO THE LANDFILL—This is the cost of hauling (but not collecting) solid waste from the Navy activity to the landfill and disposing of it there. This cost is inflated at the specified landfill inflation rate called for on Screen 6.
- 2. INFLATED PER MBTU COST OF THE FOSSIL FUEL BOILER TO WHICH THE HRI IS BEING COMPARED—This is the cost of steam to the activity which an existing PWD boiler produces or which the activity may be paying for over—the—fence service from a commercial producer, whichever service is being partly or wholly displaced by the HRI plant. This value is inflated at the energy inflation rate input on Screen 8.
- 3. TONS OF TRASH BURNED ANNUALLY--This is the amount of solid waste collected annually and sent to the HRI plant less oversized trash and that trash that must be diverted to landfill during outages after the storage facility has filled.
- 4. MBTUS PRODUCED ANNUALLY BY THE HRI (CONSIDERING NO DOWNTIME)—This value is the sum of steady state steam production, calculated from the energy content of the trash and any other fuels burned and boiler thermal efficiency less heat losses incurred while cooling and reheating the furnace following scheduled maintenance.
- 5. VIRGIN FUEL OFFSET ANNUALLY BY THE HRI IN BARRELS-OF-OIL-EQUIVALENT-This is the amount of prime fossil fuel saved by generating the quantity of steam produced (Item 4 just preceding) in the HRI assuming no unscheduled downtime. The MBtus are then converted to the standard units of barrels-of-oil-equivalent (BOE).
- 6. LANDFILL SPACE CONSERVED ANNUALLY BY THE HRI IN TONS--This is (1) the amount of solid waste that would normally be hauled to landfill if there were no HRI less (2) that solid waste generated by the HRI (ash and oversized waste) or bypassing it due to outages.
- 7. COST OF USING A BOILER TO PRODUCE THE ANNUAL NO-DOWNTIME QUANTITY OF STEAM PRODUCED BY THE HRI AND LANDFILLING ALL WASTE--This is the sum of the inflated costs to the activity for generating the annual no-downtime quantity of steam produced by the HRI and the annual cost for disposing of all the activity's trash at a landfill without the benefits of an HRI.
- 8. INFLATED TOTAL CAPITAL COST OF THE HRI--This is the capital cost of the HRI plant (screen 2) inflated at the general inflation rate from the date these costs were estimated to the time the project is funded.
- 9. UNIFORM ANNUAL COST OF THE HRI--This is the sum of operating costs for the entire economic life of the facility divided by the years of economic life. These costs take into account the cost of consumables, repair parts, sewer, insurance, pest control, labor, project lead time costs, expected modifications, residue disposal, and downtime.

- 10. ANNUAL NO-DOWNTIME COST OF THE HRI--This cost is the same as the item just preceding except that downtime costs are excluded.
- 11. DISCOUNTED LIFE CYCLE COST OF USING A BOILER TO PRODUCE THE LIFE CYCLE NO-DOWNTIME QUANTITY OF STEAM PRODUCED BY THE HRI AND LANDFILLING ALL WASTE--This is the total cost of landfilling all waste and using a conventional boiler to produce the no-downtime steam generated by the HRI both over the entire economic life of the HRI facility. This combined cost is discounted per the rate input by the user on Screen 1.
- 12. DISCOUNTED LIFE CYCLE COST OF THE HRI--This is the Uniform Annual Cost of an HRI (Item 9 above) discounted over the economic life of the project at the rate specified on Screen 1.
- 13. DISCOUNTED LIFE CYCLE COST OF AUXILIARY FUELS USED BY THE HRI--This is the annual costs for auxiliary fuels that are burned in the HRI discounted over the economic life of the HRI.
- 14. DISCOUNTED LIFE CYCLE COST OF NONCOMBUSTIBLE WASTE, ASH, AND SCHEDULED DOWNTIME WASTE DISPOSAL—This is the annual cost of landfill disposal of oversized waste and ash from the HRI and ordinary waste diverted from the HRI during scheduled downtimes. This cost is discounted over the economic life of the project.
- 15. DISCOUNTED LIFE CYCLE COST OF HRI DOWNTIME--This is the discounted life cycle cost of the annual waste tonnage diverted to landfill because of unscheduled outages multiplied by the savings for no-downtime HRI operation realized per ton of waste fired. The latter is expressed as the annual no-downtime firing rate divided into the difference between Items 7 and 10.
- 16. DISCOUNTED LIFE CYCLE COST OF THE HRI PER TON OF WASTE FIRED--This is the life cycle cost of the HRI (Item 12) divided by the product of actual (all outages included) annual trash incinerated and the years of economic life of the HRI.
- 17. DISCOUNTED LIFE CYCLE SAVINGS OF THE HRI PER TON OF WASTE FIRED—This is the discounted LC HRI savings (see Item 20 below) divided by the product of actual (all outages included) annual trash incinerated and the economic life of the HRI.
- 18. DISCOUNTED LIFE CYCLE COST OF THE HRI PER MBTU PRODUCED—This is the HRI life cycle cost (Item 12) divided by the total energy produced over the economic life of the HRI, including that for steady state steaming, reheating the furnace and while turned up above nameplate rating.
- 19. DISCOUNTED LIFE CYCLE SAVINGS OF THE HRI PER MBTU PRODUCED--This is the Life Cycle Savings of the HRI (Item 20, next below) divided by the same energy term used in Item 18.

- 20. DISCOUNTED LIFE CYCLE SAVINGS OF THE HRI--This is the energy, land-fill costs, and other savings (or losses) accrued by the HRI over its economic life and discounted to furnish an annual rate.
- 21. HRI SAVINGS-TO-INVESTMENT RATIO--This is the ratio of Item 20 to the Discounted Cost of Lead Time Expenditures, including inflated capital costs and A&E charges.
- 22. PAYBACK PERIOD IN YEARS--This is the time elapsed wherein the cumulative savings just exceed the Discounted Cost of Lead Time Expenditures.

### **DISTRIBUTION QUESTIONNAIRE**

The Naval Civil Engineering Laboratory is revising its primary distribution lists.

### **SUBJECT CATEGORIES**

- SHORE FACILITIES
- Construction methods and materials (including corrosion control, coatings)
- Waterfront structures (maintenance/deterioration control) 3
- **Utilities (including power conditioning)**
- Explosives safety
- Construction equipment and machinery
- Fire prevention and control
- Antenna technology
- Structural analysis and design (including numerical and computer techniques)
- 10 Protective construction (including hardened shelters, shock and vibration studies)
- 11 Soil/rock mechanics
- 13 BEQ
- 14 Airfields and pevements
- 15 ADVANCED BASE AND AMPHIBIOUS FACILITIES
- 16 Base facilities (including shelters, power generation, water supplies)
- 17 Expedient roads/airfields/bridges
- 18 Amphibious operations (including breakwaters, wave forces)
- 19 Over-the-Beach operations (including containerization,
- materiel transfer, lighterage and cranes) 20 POL storage, transfer and distribution
- 24 POLAR ENGINEERING
- 24 Same as Advanced Base and Amphibious Facilities, except limited to cold-region environments

- 28 ENERGY/POWER GENERATION
- 29 Thermal conservation (thermal engineering of buildings, HVAC systems, energy loss measurement, power generation)
- 30 Controls and electrical conservation (electrical systems,
- energy monitoring and control systems)
  31 Fuel flexibility (liquid fuers, coel utilization, energy from solid waste)
- 32 Alternate energy source (geothermal power, photovoltaic power systems, solar systems, wind systems, energy storage
- 33 Site data and systems integration lenergy resource data, energy consumption data, integrating energy systems)
- 34 ENVIRONMENTAL PROTECTION
- 35 Solid waste management
- 36 Hazardous/toxic materials management
- 37 Wastewater management and sanitary engineering
- 38 Oil pollution removal and recovery
- 39 Air pollution
- 40 Noise abatement
- 44 OCEAN ENGINEERING
- 45 Seafloor soils and foundations
- 46 Seafloor construction systems and operations (including diver and manipulator tools)
- 47 Undersea structures and materials
- 48 Anchors and moorings
- 49 Undersea power systems, electromechanical cables, and connectors
- 50 Pressure vessel facilities
- 51 Physical environment (including site surveying)
- 52 Ocean-based concrete structures
- 53 Hyperbaric chambers 54 Undersee cable dynamics

### TYPES OF DOCUMENTS

- 85 Techdata Sheets
- 86 Technical Reports and Technical Notes
- 82 NCEL Guide & Updates
- □ None-
- 83 Table of Contents & Index to TDS
- remove my name
- 91 Physical Security

### **INSTRUCTIONS**

The Naval Civil Engineering Laboratory has revised its primary distribution lists. The bottom of the mailing label has several numbers listed. These numbers correspond to numbers assigned to the list of Subject Categories. Numbers on the label corresponding to those on the list indicate the subject category and type of documents you are presently receiving. If you are satisfied, throw this card away (or file it for later reference).

If you want to change what you are presently receiving:

- Delete mark off number on bottom of label.
- Add circle number on list.
- Remove my name from all your lists check box on list.
- Change my address line out incorrect line and write in correction (ATTACH MAILING LABEL).
- Number of copies should be entered after the title of the subject categories you select.

Fold on line below and drop in the mail.

Note: Numbers on label but not listed on questionnaire are for NCEL use only, please ignore them.

Fold on line and staple
